ABSTRACT

Keywords: keywords

1. INTRODUCTION

It has been clear for decades that Type Ia Supernovae (SNe Ia) are caused by the thermonuclear explosions in carbon-oxygen (C/O) white dwarfs (WDs) in binary systems (see [Maoz et al. 2014](#), for a review). Nevertheless, the nature of the binary companion, as well as how it ignites the WD, remains highly uncertain.

The helium-shell (He-shell) double detonation (DDet) scenario is one of the most promising channels to produce SNe Ia. In this scenario, the WD accretes from a companion to develop a helium-rich shell, which, once becomes massive enough, could detonate. Such a detonation sends a shock wave into the C/O core to trigger a runaway thermonuclear explosion and inevitably destroy the whole WD ([Nomoto 1982a,b](#); [Woosley et al. 1986](#); [Livne 1990](#); [Woosley & Weaver 1994](#); [Livne & Arnett 1995](#)), even when the WD is below the Chandrasekhar mass (M_{Ch}).

There are several observational benchmarks for He-shell DDet triggered SNe. Shortly after the ignition of the shell, the decay of radioactive material in the helium ashes may power a detectable flash ([Woosley & Weaver 1994](#); [Fink et al. 2010](#); [Kromer et al. 2010](#)). The Fe-group elements in the ashes will blanket blue photons with wavelengths $\lesssim 5000$ Å ([Kromer et al. 2010](#)), the duration of which depends on the mass of the He-shell. For thick enough shells, [Boyle et al. \(2017\)](#) suggest that the unburnt helium could provide observational signal in near infrared (NIR) spectra, and [Polin et al. \(2021\)](#) predict significant [Ca II] emission in the nebular phase of the SNe.

Using different combos of He-shell mass and C/O core mass, one can reproduce a variety of observables in ‘normal’ SNe Ia with typical luminosities and spectral features near peak light, or peculiar sub-luminous ones ([Polin et al. 2019](#)).

For the DDet SNe that show ‘normal’ characteristics near their peaks, the mass of the He-shell is expected to

be low ($\lesssim 0.03 M_{\odot}$; [Kromer et al. 2010](#); [Sim et al. 2010](#); [Shen et al. 2018](#); [Polin et al. 2019](#)). The first DDet candidate with a thin He-shell is SN 2016jhr ([Jiang et al. 2017](#)), which exhibits an early red flash and keeps a red $g - r$ color throughout its evolution, though it show a typical absolute magnitude at peak ($M_g \approx -19$) for normal SNe Ia. The multi-band light curves involving the early flash and the major peak, as well as the optical spectrum close to the peak light, could be simultaneously fit by a near- M_{Ch} DDet model (a $1.38 M_{\odot}$ C/O core and a $0.03 M_{\odot}$ He-shell). Recently, a thinner He-shell is discovered in SN 2018aoz ([Ni et al. 2022](#)), a SN Ia showing a rapid redward color evolution within ≈ 12 hr after the first light, which could be explained by a sub- M_{Ch} DDet model (a $1.05 M_{\odot}$ C/O core and a $0.03 M_{\odot}$ He-shell). After this red excess the photometry evolution is consistent with normal SNe Ia, when the ashes of the thin He-shell becomes optically thin. To date, only a small fraction of SNe Ia have been discovered early enough for possible detection of early flashes (e.g., [Deckers et al. 2022](#)). While there could be a large underlying population of normal SNe Ia triggered by He-shell DDet, it is hard to prove so.

In contrast, if the He-shell mass is much greater than $0.03 M_{\odot}$, the ashes of the He-shell detonation could remain optically thick in a much more extended phase, resulting in the red color and low luminosity near peak light. SN 2018byg ([De et al. 2019](#)) is a prototype of thick He-shell DDet SNe. During the late stages of preparing for this paper, [Dong et al. \(2022\)](#) presented another thick shell He-shell DDet candidates, SN 2016dsg, accompanied with an archival transient OGLE-2013-SN-079 ([Inserra et al. 2015](#)). All three candidates are faint, red, and show strong line-blanketing near peak lights. [Dong et al. \(2022\)](#) also report tentative detection of unburnt helium in SN 2016dsg. The small sample size to date suggests thick shell events might be intrinsically rare.

It has been suggested that some, if not all, of the calcium-rich (Ca-rich) gap transients, a population of faint SNe with conspicuous [Ca II] emission in the nebular phase, also arise from He DDet (Dessart & Hillier 2015; De et al. 2020; Polin et al. 2021). A subclass of Ca-rich transients resemble SNe Ia near peak lights (termed Ca-Ia objects), marked by the strong Si II absorption and the absence of optical He I lines. There are only two Ca-Ia objects (SN 2016hmk and SN 2019ofm; De et al. 2020), both showing significant line-blanketing in spectra, and hence could be He-shell DDet objects. Nonetheless, they also exhibit properties of other types of sub-luminous SNe Ia, such as the strong O I absorption widely seen in 91bg-like objects (Filippenko et al. 1992) but not in other He-shell DDet candidates. Galbany et al. (2019) argue that SN 2016hmk is also consistent with a 91bg-like object arising from the deflagration of a near- M_{Ch} WD. In a word, the nature of Ca-Ia objects remain ambiguous. **Mention red Ca-Ib/c?**

In this paper, we present the observations of another promising candidate of a thick He-shell DDet SN, SN 2020jgb. This peculiar SN Ia highly resembles SN 2018byg in photometric and spectroscopic properties, and exhibits a remarkable feature in the NIR spectrum that could be attributed to the unburnt helium. In Section 2 we report the observations of SN 2020jgb, which are analyzed in Section 3, where we show its similarities with other He-shell DDet SNe and discuss the tentative He I absorption features. We use a grid of DDet models to fit the data of SN 2020jgb, and present the results in Section 5. In Section 4 we discuss the diversity in the host environments of DDet events. We draw our conclusions in Section 6.

2. OBSERVATIONS

2.1. Discovery

SN 2020jgb was first discovered by the Zwicky Transient Facility (ZTF; Bellm et al. 2019; Graham et al. 2019) on 2020 May 03.463 UT (MJD 58972.463) with the 48-inch Samuel Oschin Telescope (P48) at Palomar Observatory. The automated ZTF discovery pipeline (Masci et al. 2019) detected SN 2020jgb using the image-differencing technique of Zackay et al. (2016). The candidate passed internal thresholds (e.g., Mahabal et al. 2019; Duev et al. 2019), leading to the production and dissemination of a real-time alert (Patterson et al. 2019) and the internal designation ZTF20aayhacx. It was detected with [Chang: $g_{\text{ZTF}} = 19.86 \pm nn.nn \text{ mag}$] at $\alpha_{\text{J2000}} = 17^{\text{h}}53^{\text{m}}12^{\text{s}}.651$, $\delta_{\text{J2000}} = -00^{\circ}51'21''.81$ and announced to the public in Fremling (2020). The host galaxy, PSO J175312.663+005122.078, is a dwarf galaxy, to which SN 2020jgb has a projected offset of

only $0.3''$. The last non-detection limits the brightness to $r_{\text{ZTF}} > 20.7 \text{ mag}$ on 2020 April 27.477 (MJD 58966.477; 5.99 days before the first detection). This transient was identified as a SN Ia by Dahiwalé & Fremling (2020) due to the prominent Si II absorption features and a lack of any H features in the spectrum obtained on 2020 May 28.468. [Chang: These details are not given in that report, I would simply say - classified as a SN Ia in ...]

2.2. Optical Photometry

SN 2020jgb was monitored in the g_{ZTF} and r_{ZTF} -bands by ZTF as part of its ongoing Northern Sky Survey (Bellm et al. 2019). We adopt a Galactic extinction of $E(B - V) = 0.404 \text{ mag}$ (Schlafly & Finkbeiner 2011), and correct all photometry using the Fitzpatrick (1999) extinction model. We assume there is no additional extinction in the host galaxy. This assumption is supported by the lack of Na I D absorption at the redshift of the host galaxy, though see Poznanski et al. (2011) for caveats on the use of Na I D absorption as a proxy for extinction.

[Chang: it is a little strange to discuss the redshift in a subsection about photometry – wherever this paragraph goes I would start by stating the observed redshift as measured from the host spectrum. Then discuss peculiar velocities to determine μ .] To get the distance modulus to SN 2020jgb, we use the 2M++ model (Carrick et al. 2015) to obtain a peculiar velocity towards its host galaxy, PSO J175312.663+005122.078, to be 179 km s^{-1} . This, combined with the recession velocity in the frame of the cosmic microwave background¹ (CMB) $v_{\text{CMB}} = 9136 \text{ km s}^{-1}$, give a net Hubble recession velocity is 9307 km s^{-1} [AAM: $\pm 250 \text{ km s}^{-1}$]. Adopting $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_M = 0.3$, and $\Omega_\Lambda = 0.7$, we estimate the luminosity distance to SN 2020jgb to be 136.1 Mpc , which yields a distance modulus of $\mu = 35.66$.

The forced photometry light curves (absolute magnitudes) in g_{ZTF} - and r_{ZTF} -bands are shown in Figure 1, in which we show all the measurements with $\text{SNR} > 2$. [Chang: Should point to ZTF forced light curve service as a reference here - probably also make sense to cite Miller et al. in prep since I made the light curve]

2.3. Optical Spectroscopy

We obtained optical spectroscopic follow-up of the object from ~ -10 days to $\sim +150$ days relative to the r_{ZTF} -band peak, using the Spectral Energy Distribution Machine (SEDm; Blagorodnova et al. 2018) on the auto-

¹ See https://ned.ipac.caltech.edu/velocity_calculator.

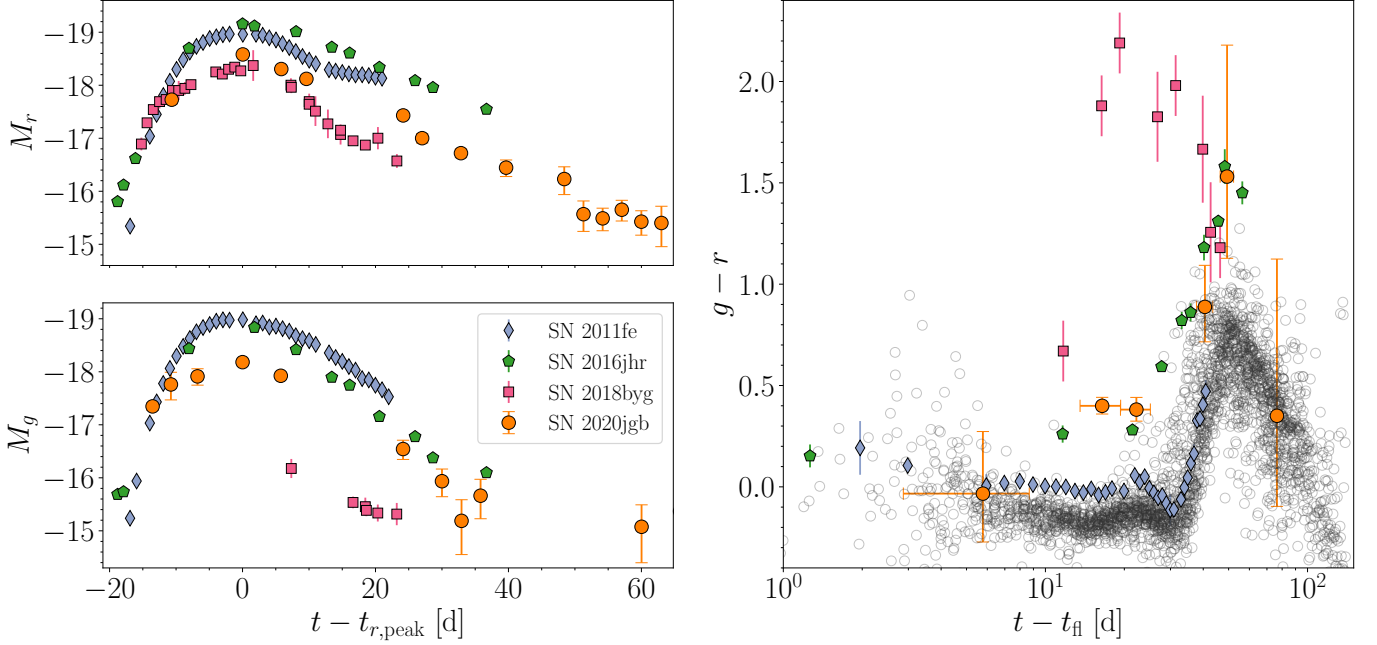

Figure 1. *Left:* Comparison of the multi-color light curves of SN 2020jgb with the normal SN Ia SN 2011fe, the thin shell DDet candidate SN 2016jhr, and the thick shell DDet candidate SN 2018byg. The upper (lower) panel shows the evolution in g -band (r -band) absolute magnitudes. *Right:* comparison of $g - r$ color evolution to SN 2011fe and SN 2018byg, as well as 62 normal SNe Ia (open circles) with prompt observations within 5 days of first light by ZTF (Bulla et al. 2020).

mated 60 inch telescope (P60; Cenko et al. 2006) at Palomar Observatory, the Kast Double Spectrograph (Miller & Stone 1994) at the Shane 3 m Telescope, the Andalu-cia Faint Object Spectrograph and Camera (ALFOSC)² installed at the Nordic Optical Telescope (NOT), the Double Beam Spectrograph (DBSP) on the 200 inch Hale telescope (P200; Oke & Gunn 1982), the Low Resolution Imaging Spectrograph (LRIS) on the Keck I telescope (Oke et al. 1995). Spectra were reduced using standard procedures (e.g., Matheson et al. 2000). Details of the spectroscopic observations are listed in Table 1, and the spectral sequence is shown in Figure 2.

On 2022 March 31, two years after the transient faded, we also took a spectrum for its host galaxy using the DEep Imaging Multi-Object Spectrograph (DEIMOS) on the Keck II telescope (Faber et al. 2003), for a total integration time of 3200 s. The spectra were reduced with the PyPeIt Python package (Prochaska et al. 2020).

2.4. Near-infrared (NIR) Spectroscopy

We obtained one NIR ($0.8\text{--}2.5\mu\text{m}$) spectrum of SN 2020jgb using the Gemini near-infrared spectrometer (GNIRS; Elias et al. 1998) on the Gemini North tele-

NOTE—Phase is measured relative to the r_{ZTF} -band peak in the host galaxy rest frame. The resolution R is reported for the central region of the spectrum.

scope on 2020 June 9 (~ 22 days after r_{ZTF} -band peak), for an integration time of 2400 s. The GNIRS spectrum was reduced with PyPeIt.

3. ANALYSIS

3.1. Photometric Properties

² <https://www.not.iac.es/instruments/alfosc/>

Figure 2. *Left:* optical spectral sequence of SN 2020jgb. Rest frame phases (days) relative to the r_{ZTF} -band peak and instruments used are posted next to each spectrum. The spectra are after Galactic extinction correction are shown in grey. The black lines are binned spectra with a bin size of 10 \AA , except for the SEDM spectra, whose resolution is lower than the bin size. In the last two spectra, we have subtracted the light from the host galaxy. Only regions with $\text{SNR} > 2.5$ after binning are plotted. *Right:* spectral comparison with SN 2018byg (sub-luminous He-shell DDet) and SN 2004da (normal luminosity). Spectra for SN 2004da and SN 2018byg are obtained from the WISEReP repository (Yaron & Gal-Yam 2012). [Chang: should cite the original sources for the spectra. Also - we should mark regions with telluric absorption that is not corrected]

SN 2020jgb exhibited a fainter light curve than normal SNe Ia. In Figure 1, we compare the photometric properties of SN 2020jgb with the nearby, well-observed SN 2011fe (Nugent et al. 2011) and two He-shell DDet candidates, including the normal-luminosity thin shell candidate SN 2016jhr (Jiang et al. 2017) and the sub-luminous thick shell candidate SN 2018byg (De et al. 2019), with available photometric data on the Open Supernova Catalog³ (Guillochon et al. 2017). [Chang: were all these light curves corrected for reddening? I thought 11fe peaked brighter than -19. Also might be worth a small note stating that these were all observed in different g/r bands, which also means it's worth noting (some-

where not necessarily here) that K -corrections have not been performed]

While the observational coverage is sparse in the rise to maximum light, from Figure 1 it is clear that SN 2020jgb is less luminous than normal SNe Ia (e.g., SN 2011fe). Furthermore, there is a flatter evolution in the r_{ZTF} evolution between -14 d and maximum light for both SN 2020jgb and SN 2020jgb than there is for SN 2011fe.

In the right panel of Figure 1, we compare the color evolution ($g-r$) of these objects relative to the measured time of first light t_{fl} , accompanied by 62 normal SNe Ia (open circles) observed within 5 days of t_{fl} by ZTF (from Bulla et al. 2020). For SN 2020jgb the early rise of the light curve was not well sampled, so we estimate t_{fl} as the midpoint of the first detection and the last non-

³ See <https://github.com/astrocatalogs/supernovae>.

Figure 3. The NIR spectra of SN 2020jgb and two SNe Ia with normal maximum luminosity (SN 2004ab and SN 2004da, [Marion et al. 2009](#)), taken about three weeks after the peak. For each spectrum, the continuum at $\gtrsim 1.2 \mu\text{m}$ is significantly reshaped by the Fe-group blanketing (emission features, blue vertical lines) and Co II absorption (pink vertical lines). Spectra for SN 2004ab and SN 2004da are obtained from [Marion et al. \(2009\)](#).

detection. We adopt an uncertainty on this estimate of 3 days. All three DDet candidates are undoubtedly redder than normal SNe Ia. At peak light, SN 2020jgb was not as red as the extreme case, SN 2018byg ($g_{\text{ZTF}} - r_{\text{ZTF}} \approx 2.2 \text{ mag}$ [[Chang: I think the colors for 18byg are from P60 so they aren't the ZTF filters](#)]), but exhibited a similar color as SN 2016jhr ($g - r \approx 0.5$).

3.2. Optical Spectral properties

In Figure 2, we show the optical spectral sequence of SN 2020jgb, and compare its spectra with some other SNe Ia near peak luminosity. For the spectra obtained after +100 d there is clear contamination from the host-galaxy, including the presence of narrow emission lines. For these spectra we subtract the galaxy light as measured in the DEIMOS spectrum from 2022 (see Section 2.3). The earliest spectrum was obtained by SEDM ≈ 10 days before the r_{ZTF} -band peak. We only show portions of the spectrum where the $\text{SNR} > 2.5$, where the continuum is almost featureless with some marginal detection of the Si II $\lambda 6355$ at $\approx 6100 \text{ \AA}$, the trademark of SNe Ia. In subsequent spectra the Si II features become more prominent and are clearly detected through +12 d. We measure Si II expansion velocities with a Gaussian profile following a similar procedure as in [Maguire et al. \(2014\)](#). The fitting region is selected by visual inspection. The continuum is assumed to be linear. Within the model, the continuum flux density at the blue and red

edges are free parameters for which we adopt a normal distribution as a prior. The mean and standard deviation for the normal are the observed flux density and its uncertainty, respectively, at each edge of the fitting region. [[Chang: Is this done prior to the Gaussian fit? I thought the continuum was estimated at the same time as the Gaussian profile?](#)] The absorption feature is then normalized by the continuum and fit to a single Gaussian profile with three parameters (amplitude, mean velocity, velocity dispersion). [[Chang: what priors for these parameters?](#)] Posteriors of these five parameters are sampled with `emcee` ([Foreman-Mackey et al. 2013](#)) using the Markov chain Monte Carlo (MCMC) method. We find the mean expansion velocity is $\approx 11,500 \text{ km s}^{-1}$ near maximum light.

In many SNe Ia the Ca II infrared triplet (IRT) absorption has two distinct components. Following, [Maguire et al. \(2014\)](#), we refer to these components as photospheric-velocity features (PVFs) and high-velocity features (HVF) [[Chang: double check that Kate was first to use this terminology](#)]. The PVFs originate from the main line-forming region with typical photospheric (i.e., bulk ejecta) velocities, while the HVFs are blueshifted to much shorter wavelengths, indicating significantly higher (by greater than $\sim 6000 \text{ km s}^{-1}$) velocities than typical PVFs ([Silverman et al. 2015](#)). Figure 2 shows that SN 2020jgb has prominent HVFs of Ca II IRT. The HVFs are visible in our first spectrum of

SN 2020jgb, and remain prominent through +36 days. Using a similar technique in modeling the Si II features, we fit the HVFs with multiple Gaussian profiles assuming each line in the triplet can be approximated by the same profile (i.e., same amplitude and velocity dispersion), and obtained a best-fit expansion velocity $\gtrsim 26,000 \text{ km s}^{-1}$. A clear delineation between the HVFs and PVFs is visible ≈ 4 days before peak light. Since then we fit the broad absorption features with two different velocity components simultaneously. The velocity of HVFs slightly declines but stays above $\approx 24,000 \text{ km s}^{-1}$, and the velocity of PVFs declines from $\approx 11,000 \text{ km s}^{-1}$ to $\approx 9,000 \text{ km s}^{-1}$. As in normal SNe Ia, the relative strength between the HVFs and PVFs decreases with time. [Chang: might be worth a figure - especially if we have this measured for several other DDet now]

The nebular phase spectra of SN 2020jgb are dominated by the Fe-group elements, showing some enhancement in flux between ≈ 4500 and $\approx 6000 \text{ \AA}$. We did not detect any emission feature related to [Ca II] $\lambda\lambda 7291, 7324$, which is a hallmark for Calcium-rich gap transients and is also prominent in a few DDet candidates (e.g., SN 2016hmk and SN 2019ofm; De et al. 2020).

The optical spectral evolution of SN 2020jgb resembles that of SN 2018byg, a sub-luminous DDet candidate with a potentially thick helium shell. [Chang: I think we can safely call this a DDet, and not a candidate] At early times, both SNe were relatively blue and featureless with broad and shallow Ca II IRT absorption. As they evolved closer to maximum light, they developed strong continuous absorption bluewards of $\approx 5000 \text{ \AA}$, while the Si II $\lambda 6355$ and the Ca II IRT became more prominent. S II was not detected in either object. In the DDet scenario, a large amount of Fe-group elements will be synthesized in the outer regions of the ejecta, which will cause significant line-blanketing near maximum light (Kromer et al. 2010; Polin et al. 2019), and also high velocity intermediate-mass elements like Ca II (Fink et al. 2010; Kromer et al. 2010). The similarity between SN 2020jgb and SN 2018byg, makes SN 2020jgb another promising DDet SN candidate.

SN 2004da is a normal SN Ia that shows similarities to SN 2020jgb in the NIR (Section 3.3), however, the two SNe are extremely different in the optical (Figure 2). From this comparison it is clear that SN 2020jgb is not a normal SN Ia.

3.3. NIR Spectral properties

The NIR spectrum of SN 2020jgb is compared with two normal SNe Ia at a similar phase in Figure 3 (data for SNe 2004ab and 2004da from Marion et al. 2009). SN 2020jgb shows a strong absorption feature at

$\sim 0.99 \mu\text{m}$, which is not seen in normal SNe Ia. This feature was still significant two weeks later, as detected by LRIS on Keck (see Figure 4), though it was only partially covered. Aside from this prominent feature, SN 2020jgb resembles normal SNe Ia in NIR band. The shape of the continuum redwards to $\approx 1.2 \mu\text{m}$ is significantly altered by line-blanketing from Fe-group elements. Just like normal SNe Ia, SN 2020jgb shows an enhancement of flux at about 1.3, 1.55, 2.0, 2.1, and $2.25 \mu\text{m}$, accompanied by several Co II absorption lines. It is especially similar to SN 2004da at +25 days after maximum light as the steep increase in flux at $\approx 1.55 \mu\text{m}$, known as the *H*-band break (Hsiao et al. 2019), has become less prominent.

In a sample of [Chang: NNN] SNe Ia with NIR spectra obtained more than 15 days after peak, not a single one shows prominent absorption features around $1 \mu\text{m}$ Marion et al. (2009). We have investigated several potential identifications for this feature (see below), however, none of them provide a fully satisfying explanation.

The most tantalizing possibility is that the absorption is due to He I $\lambda 1.0830 \mu\text{m}$ [Chang: I think (?) the λ convention does not specify units because it is assumed to be \AA , in which case this would just be 10,830. Worth double checking]. If SN 2020jgb is a DDet SN, then unburned He could lead to observed absorption in the spectrum, as shown in the sub-Chandrasekhar-mass He-shell DDet models of Boyle et al. (2017). Figure 4 shows that the $1 \mu\text{m}$ feature, if associated with He I $\lambda 1.0830 \mu\text{m}$, has a high velocity ($\sim 26,000 \text{ km s}^{-1}$), especially considering the phase of the SN. The Ca II IRT also exhibits similarly high velocities at the same phase ($\sim 24,000 \text{ km s}^{-1}$), suggesting it is not impossible to see very high absorption velocities at this phase. The expansion velocity in the ejecta is roughly linearly proportional to the radius, so such a high velocity indicates that both the Ca II IRT and the tentative He I absorption line form far outside the normal photosphere, which has a velocity of only $\approx 10,000 \text{ km s}^{-1}$. In this sense, the He-shell DDet scenario, in which the unburnt helium is located in the outermost ejecta, is indeed supported.

We cannot claim an unambiguous detection of He I, however, as our spectra lack definitive absorption from other He features that we would expect to be prominent, such as He I $\lambda 2.0581 \mu\text{m}$. Considering a line velocity of $\approx 26,000 \text{ km s}^{-1}$ and a host galaxy redshift of 0.0309, this line will be blueshifted to $\approx 1.95 \mu\text{m}$ in the observer frame, so will be strongly blended by the strong telluric lines within 1.8-2.0 μm . After telluric correction, the signal to noise ratio reaches ~ 5 , with which we still cannot see any significant absorption feature. An upper limit

Figure 4. Spectra of SN 2020jgb, SN 2018byg, and SN 2016hbk in the velocity space, comparing the Ca II IRT absorption features (upper panels) and the $1\mu\text{m}$ features assuming they are associated with He I $\lambda 1.0830\mu\text{m}$ (lower panels). The red dashed lines mark the minimum of each $1\mu\text{m}$ feature. Data for SN 2018byg and SN 2016hbk are obtained from the WISEReP repository (Yaron & Gal-Yam 2012).

of the equivalent width is determined to be $<2\%$ of the $1.0830\mu\text{m}$ line, while theoretically, the $2.0581\mu\text{m}$ line is supposed to be only a factor of 6-12 weaker, depending on temperature (Marion et al. 2009). Another fact is that the $1\mu\text{m}$ feature is as strong as the He I $\lambda 1.0830\mu\text{m}$ in many helium-rich core-collapse supernovae, say, Type Ib supernovae, in which the He I $\lambda 2.0581\mu\text{m}$ is weaker than the $1.0830\mu\text{m}$ line yet still prominent (Shahbandeh et al. 2022). If the $1\mu\text{m}$ feature is associated with He I, it would be very unusual if the $2\mu\text{m}$ feature is not seen at all, even if somehow blended by the telluric lines. [Chang: There should be a note here about the strength of the lines in the Boyle paper... for one of their models there is no obvious 2 micron absorption] [AAM: that model is for ‘normal’ SNe Ia]

Other possible identifications include Mg II $\lambda 1.0927\mu\text{m}$, C I $\lambda 1.0693\mu\text{m}$, and Fe II $\lambda 1.0500\mu\text{m}$ & $\lambda 1.0863\mu\text{m}$. The Mg II $\lambda 1.0927\mu\text{m}$ line is prevalent in the NIR spectra of SNe Ia, but usually disappears within a week after peak (Marion et al. 2009), while the $1\mu\text{m}$ feature was still visible over a month after the peak in the Keck LRIS spectrum. The required radial velocity is $\approx 30,000\text{ km s}^{-1}$, $\approx 20\%$ faster than the HVFs of Ca II IRT at the same phase. While such a high velocity for Mg II has never been seen in other SNe

Ia, since high-velocity intermediate-mass elements like magnesium and calcium can be synthesized by the detonation of helium shell (Shen & Moore 2014), the Mg II origin of the $1\mu\text{m}$ feature cannot be strictly ruled out. But if we attribute this $1\mu\text{m}$ feature to high-velocity Mg II, we would expect an even stronger $\lambda 0.9227\mu\text{m}$ line to be blueshifted to the red edge of the Ca II IRT, which is not detected. Given the strength of the $1\mu\text{m}$ feature, the $0.9227\mu\text{m}$ line should not be completely obscured by the Ca II IRT features.

C I $\lambda 1.0693\mu\text{m}$ is not observed as frequently as Mg II $\lambda 1.0927\mu\text{m}$ in SNe Ia. Hsiao et al. (2019) presented a sample of five SNe Ia with C I detections, showing the C I feature is strongest for fainter, fast-declining objects. However, in their sample, the C I feature is a pre-maximum feature which fades away as the luminosity peaks, so the discrepancy in phase is large. The required expansion velocity $\approx 22,000\text{ km s}^{-1}$, which is overwhelmingly faster than the estimated carbon velocity for the sample in Hsiao et al. (2019) ($\sim 10,000\text{--}12,000\text{ km s}^{-1}$), but still consistent with the HVFs of Ca II IRT. Nonetheless, no significant carbon absorption is detected in the optical band.

The Fe II features in SNe Ia usually start to develop roughly three weeks after the peak, which is about the

same phase as we obtained our GNIRS spectrum. Two Fe II lines, $\lambda 0.9998 \mu\text{m}$ and $\lambda 1.0500 \mu\text{m}$, are actually visible on the blue/red wings of the $1 \mu\text{m}$ feature. The Fe II $\lambda 1.0863 \mu\text{m}$ line is not yet seen in the GNIRS spectrum. They correspond to an expansion velocity of $\approx 8,000 \text{ km s}^{-1}$, which is consistent with the PVFs of the Ca II IRT at the same epoch. They also match the same two lines for normal SNe Ia (Marion et al. 2009), making the identification more reliable. Obviously, these two Fe II features are wider and shallower than the strong feature between them. We fit the $1 \mu\text{m}$ feature with three Gaussian profiles. Two of them are set to be the blueshifted Fe II $\lambda 0.9998 \mu\text{m}$ and $\lambda 1.0500 \mu\text{m}$, and the other is an uncorrelated Gaussian profile which mainly describes the absorption in the center. We find that the shallower and wider Fe II lines only make up $\sim 40\%$ of the total equivalent width, and the rest $\sim 60\%$ comes from the central feature, which cannot be accounted for by any Fe II feature at the same velocity. Given the similarity of the Fe-group line-blanketing between the GNIRS spectrum with the spectrum of SN 2004da at +25 days, the distribution of Fe-group elements inside each supernova ejecta should be somehow similar as normal SNe Ia, so the central region of the $1 \mu\text{m}$ feature is not likely to be associated with Fe II either.

While the nature of the $1 \mu\text{m}$ feature remains uncertain, other He-shell DDet candidates also seem to show similar complexity in this region. In the currently small sample of six candidates, three objects (SN 2016jhr, SN 2018aoz, and SN 2019ofm) do not have any available NIR spectra, while the other three (at quite different phases though) all exhibit strong absorption features near $1 \mu\text{m}$, as shown in Figure 5. SN 2016hmk has two deep absorption features around $1.02 \mu\text{m}$ and $1.17 \mu\text{m}$, both are at a longer wavelength than the $1 \mu\text{m}$ feature in SN 2020jgb. Galbany et al. (2019) suggest both of them could be caused by Fe II, though they are deeper than in other SNe Ia. The velocity of the $1.02 \mu\text{m}$ feature is $\approx 21,000 \text{ km s}^{-1}$ assuming a He I $\lambda 1.0830 \mu\text{m}$ origin, which, just like SN 2020jgb, is about the same as the HVFs of the Ca II IRT in the optical spectra (see Figure 4). The PVFs of the Ca II IRT of both SNe have a similar expansion velocity of $\approx 10,000 \text{ km s}^{-1}$. Such a consistency in velocities is also seen in SN 2018byg (see Figure 4). But given the exotic width and lower signal-to-noise ratio in the $1 \mu\text{m}$ feature, the exact line velocity is hard to determine. It is likely to be a mixture of several different lines.

Dong et al. (2022) recently proposed another thick He-shell DDet candidate, SN 2016dsg, with an absorption line around $0.97\text{--}1.05 \mu\text{m}$ in a low-SNR NIR spec-

trum at +16.6 days⁴. Assuming He I $\lambda 1.0830 \mu\text{m}$ origin, the minimum of the absorption profile (at $\approx 1.03 \mu\text{m}$, see Figure 4 in Dong et al. 2022) corresponds to an expansion velocity of $\approx 15,000 \text{ km s}^{-1}$. This is lower than the $1 \mu\text{m}$ features in SN 2020jgb and SN 2016hmk assuming their He I origin. Interestingly, SN 2016dsg shows the least prominent HVFs of Ca II IRT among the four, which also has a low velocity of $\approx 15,000 \text{ km s}^{-1}$. Once again, the scenario where both the unburnt helium and the high velocity calcium are located at the outermost shell is favored.

Unfortunately, none of the spectra for SN 2016dsg, SN 2016hmk, or SN 2018byg covers the $2 \mu\text{m}$ region, thus it is not possible to identify the presence of helium decisively. But if the $1 \mu\text{m}$ feature of these objects are of the same origin, they are more likely to be correlated with the high velocity ejecta lying in the outmost region in the supernovae, because at least for SN 2020jgb and SN 2016hmk, the difference in their photospheric velocities cannot explain the discrepancy in their line velocities of the $1 \mu\text{m}$ feature. Then helium is still a promising candidate to cause strong absorption near $1 \mu\text{m}$ for these sub-luminous He-shell DDet SNe Ia.

In conclusion, from all the He-shell DDet candidates with NIR spectra available, we have detected strong absorption features near $1 \mu\text{m}$, which is not seen in normal SNe Ia. Indeed, these candidates have their NIR spectra taken at different epochs, hence each $1 \mu\text{m}$ feature can be of completely unrelated origin. Had they all originate from He I $\lambda 1.0830 \mu\text{m}$, there would still be large diversity in the corresponding expansion velocities. This is to be confirmed in a more complete NIR spectral sequence in future He-shell DDet SNe Ia. Nonetheless, the seemingly ubiquitous $1 \mu\text{m}$ feature in various phases is possibly a distinctive attribute against normal SNe Ia.

4. HOST GALAXY

We obtained a DEIMOS spectrum of the host galaxy, PSO J175312.663+005122.078, on 2022 March 31. The host exhibits strong, narrow emission lines including H α , H β , [N II] $\lambda 6583$, [O III] $\lambda 5007$, and [S II] $\lambda 6716$ & $\lambda 6731$. By fitting all these emission features with Gaussian profiles we obtain an average redshift of $z = 0.0309 \pm 0.0003$. With the diagnostic emission line equivalent width ratios ($\log [\text{N II}]/\text{H}\alpha = -1.19 \pm 0.07$ and $\log [\text{O III}]/\text{H}\beta = 0.53 \pm 0.06$), the host is consistent with star-forming galaxies in the BPT diagram (Baldwin et al. 1981; Veilleux & Osterbrock 1987).

⁴ SN 2016dsg was discovered declining. The phase is relative to the discovery time.

Figure 5. The NIR spectra (9000 to 13000 Å) of a few normal SNe Ia (SN 2011fe and SN 2004da) and three He-shell DDet candidates, which are all sub-luminous SNe Ia (SN 2016hnk, SN 2018byg, and this source, SN 2020jgb). Other than the spectrum of SN 2004da, all spectroscopic data are obtained from the WISEReP repository (Yaron & Gal-Yam 2012).

We model the detailed properties of the host galaxy using *prospector* (Johnson et al. 2021), a package for principled inference of stellar population properties using photometric and/or spectroscopic data. The input data included the Galactic extinction corrected DEIMOS spectrum, as well as the archival photometric data from the Panoramic Survey Telescope and Rapid Response System (Pan-STARRS; Chambers et al. 2016, r , i , z Kron magnitudes) and the VISTA Hemisphere Survey (VHS; McMahon et al. 2013, J and K_s Petrosian magnitudes) [Chang: didn't we change to LS?]. In the best fit, the estimated stellar mass is $\log(M_* [M_\odot]) = 7.79^{+0.07}_{-0.06}$, and the specific star-formation rate (sSFR) is $\log(\text{sSFR} [\text{yr}^{-1}]) = -10.25^{+0.09}_{-0.08}$, with the uncertainties denoting the 68% credible regions.

In Figure 4, we show the sSFR and the stellar mass for the host galaxies of our [Chang: these are not all

“ours” - others discovered several of these candidates] six He-shell DDet candidates. Again using *prospector*, we fit the stellar properties for all the other candidates with optical spectra from the Sloan Digital Sky Survey (SDSS; York et al. 2000) and photometry from the DESI Legacy Imaging Surveys (Dey et al. 2019, g , r , z , W_1 , W_2 , W_3 , W_4 magnitudes). With mid-infrared photometry available, *prospector* can better estimate the overall dust extinction in the host galaxy and the contribution of an active galactic nucleus (AGN) to the spectral energy distribution (SED). Unfortunately, two (SN 2016hnk and SN 2019ofm) out of six hosts are close-by ($z \lesssim 0.03$) late-type galaxies with extended, spatially resolvable spiral structures. In both surveys, only photons from their red, concentrated bulges were fed to the detectors, while the lights from the blue, diffusive star-forming regions were completely missed. We would inevitably underestimate their SFR should we naively fit the SEDs from these surveys. Therefore, for the host of SN 2016hnk, we adopt the results in Galbany et al. (2019) as part of the PMAS/PPak Integral-field Supernova Hosts Compilation (PISCO; Galbany et al. 2018), where the photons from the H II regions in the spiral arms were also collected using integral field spectroscopy (IFS). For the host of SN 2019ofm, there are no IFS data available, so we still show our best-fit stellar mass and sSFR in Figure 4, with the caveat that the sSFR should be regarded as a lower limit. The host of SN 2018aoz (NGC 3923) is a local ($z = 0.00580$) early-type galaxy and is outside the SDSS footprint, so we adopt its stellar population properties from the Census of the Local Universe (CLU) catalog [AAM: References?].

The recent study on SN 2016dsg and OGLE-2013-SN-079 (Dong et al. 2022) enlarges the sample of thick He-shell DDet candidates. Similar to SN 2018byg, both of them reside in the outskirts of early-type galaxies which are >10 kpc away from the host centers, indicating an origin in old stellar populations. A projected host offset $\gtrsim 10$ kpc is also seen in SN 2016jhr, SN 2018aoz, and SN 2019ofm, whereas the hosts of SN 2016jhr and SN 2019ofm are star-forming galaxies. SN 2016hnk, on the contrary, has a smaller projected host offset of ~ 4 kpc and a potential origin in an H II region with ongoing star-formation (Galbany et al. 2019). SN 2020jgb is the first He-shell DDet candidate in a star-forming dwarf galaxy. It has the smallest projected physical offset (~ 0.2 kpc) yet to know.

Given the limited sample size yet, the host environments of the He-shell DDet candidates have started to show diversity. This is true for both thin He-shell objects of normal luminosity (SN 2016jhr in a star-forming host; SN 2018aoz in a quenched host) and thick He-shell,

sub-luminous objects (SN 2020jgb in a star-forming host; SN 2016dsg, SN 2018byg, and OGLE-2013-SN-079 in quenched hosts), even when the natures of SN 2016hnk and SN 2019ofm remain ambiguous. In this sense, the He-shell DDet sample resembles the SNe Ia population in general, which can occur in both star-forming and quenched galaxies (e.g., Sullivan et al. 2006; Smith et al. 2012). But such a diversity in host environments is very different from some other types thermonuclear supernovae, such as Type-Iax supernovae (SNe Iax) which almost only appear in star-forming galaxies, or SN 1991bg-like and SN 2002es-like objects, which prefer old stellar environments (see the review in Jha et al. 2019). Most SNe in our sample show a relative large host galaxy offset, which has also been observed in many Ca-rich transients (Lunnan et al. 2017), with typical projected offsets being ~ 10 -100 kpc (De et al. 2020). Some dynamical formation channels have been proposed to explain the remote locations of Ca-rich transients, such that WD binaries would need to be hardened and ejected by globular clusters (Shen et al. 2019) or supermassive black holes (Foley 2015) before explosions, which may also be the case for some, if any all, of He-shell DDet SNe. Other DDet SNe, SN 2020jgb being the most unambiguous example, are located in star-forming regions and are thus highly likely to be formed *in situ*. Two recently discovered subdwarf B binaries with WD companions which were found in young stellar populations could be promising progenitor systems (Geier et al. 2013; Kupfer et al. 2022).

The robust detection of He-shell DDet SNe in star-formation regions also agrees with independent studies on SNe Ia progenitors using stellar metallicity observations. de los Reyes et al. (2020), by studying the manganese abundances in dwarf spheroidal satellites of the Milky Way, argue that sub- M_{Ch} SNe Ia dominates the chemical evolution of a galaxy, while near- M_{Ch} SNe tend to take over at later times, indicating that observationally, sub- M_{Ch} SNe Ia might have a stronger preference towards younger stellar populations than near- M_{Ch} SNe Ia. He-shell DDet is one of the most favored channel to ignite a sub- M_{Ch} WD, which could produce both normal and sub-luminous SNe Ia. Consequently, we would expect the majority of exploded SNe Ia in star-forming galaxies (at least the dwarfs) would undergo DDet. We note that while SN 2020jgb is the first confirmed He-shell DDet SN in a star-forming dwarf, which indicates that thick shell DDet SNe might be intrinsically rare, the same may not be true for thin shell DDet SNe since they would look just as *normal* in both photometric and spectroscopic evolution a few days after explosions (Ni et al. 2022). Unfortunately, few of them are observed in

Figure 6. The specific star-formation rate (sSFR) and the stellar mass for the host galaxies of He-shell DDet candidates. The properties for the hosts of SN 2016hnk and SN 2018aoz are taken from Galbany et al. (2019) and the CLU catalog [AAM: References?], respectively. For the sSFR in the host of SN 2019ofm, only a lower limit is shown (the triangle). The background is a sample of galaxies from the SDSS MPA-JHU DR8 catalog (Kauffmann et al. 2003; Brinchmann et al. 2004). Galaxies with BPT classification as AGNs or LINERs are excluded, since certain spectral features (e.g., H α emission) due to nuclear activities might be misinterpreted as star formation.

such an early phase to date (SN 2016jhr and SN 2018aoz being two of them), thus we might have missed a great number of He-shell DDet SNe. With more efficient time domain surveys kicking in in the near future and prompt follow-up observations being increasingly available (**also need some references**), a systematic studies on the infant SNe Ia will help confirm this implication. [AAM: Do you think we should put this paragraph here or in the discussion section?]

5. MODEL COMPARISONS

A few sentences from Abi describing the models.

In Figure 5, we show the comparison of the photometric and spectroscopic features of SN 2020jgb with DDet models from Polin et al. (2019). The peak luminosity reflects the total progenitor mass (C/O core + He shell), and we find models with a total mass of $0.95 M_{\odot}$ generally reproduce the *r*-band peak brightness well. Thus in Figure 5, the total mass is fixed to be $0.95 M_{\odot}$ in all models. The overall *r*-band photometric evolution is best fit by the model with a $0.87 M_{\odot}$

C/O core and a $0.08 M_{\odot}$ He shell, while all three models underestimate the g -band brightness after the peak. This deviation may be attributed to a variety of factors on handling the explosion and radiative transfer. First, throughout the simulations we assume local thermodynamic equilibrium (LTE), which is not valid once the ejecta becomes optically thin. Typically the bulk ejecta of a sub-Chandrasekhar SNe Ia remains optically thick for ~ 30 days since the explosion. But in modeling the brightness g -band, the LTE assumption is even more tricky, because the major opacity in g -band comes from the Fe-group line-blanketing in the outermost ejecta, where the optical depth may evolve differently from that at the photosphere. Hence the LTE condition may quickly become inapplicable. Furthermore, our 1-D He shell model is not capable to capture the multi-dimensional effects in the explosion such as asymmetries. The viewing angle is known to have a significant influence on the observed light curves (Kromer et al. 2010; Sim et al. 2012; Gronow et al. 2020; Shen et al. 2021), especially in bluer bands where the line-blanketing depends sensitively on the distribution of He-shell ashes (Shen et al. 2021). In previous studies on other DDet objects, the g -band brightness is systematically under-predicted shortly after the peak, despite the fact that redder bands can be fit decently (e.g. Jiang et al. 2017; Jacobson-Galán et al. 2020).

The model which best fits the photometry ($0.87 M_{\odot} + 0.08 M_{\odot}$) also reproduces the major absorption features (e.g., Fe-group line-blanketing, Si II $\lambda 6355$, PVFs of Ca II IRT) and the corresponding expansion velocities near the peak light. However, we are not able to fit the continua in g -, r -, and z -bands simultaneously, and the strong Ca II HVFs are not seen in the best-fit spectrum. These discrepancies could also be due to the asymmetry in the DDet, that SN 2020jgb was observed fairly close to the ignition point, where the abundances of Fe-group elements and high velocity calcium synthesized in the shell could be much higher than an angle-averaged 1-D model would predict. In addition, the predicted Si II $\lambda 5972$ does not show up in the observed spectrum.

Conclusions from the model comparison.

6. DISCUSSION AND CONCLUSIONS

In the paper, we have presented the observations of SN 2020jgb, a sub-luminous SN Ia. Putting together its unusual red colors and strong line-blanketing in the spectra near peak light, we show its peculiar nature as a SN Ia. It bears a high degree of resemblance to SN 2018byg (De et al. 2019), whose observational properties could be explained by the detonation of a shell of helium on a sub- M_{Ch} WD. Fitting the light curve of

SN 2020jgb to a grid of models in Polin et al. (2019), we show a $\approx 0.87 M_{\odot}$ WD beneath a $\approx 0.08 M_{\odot}$ He-shell would be a reasonable estimate on its progenitor properties.

A high-SNR NIR spectrum obtained three weeks after the peak light shows a prominent absorption feature near $1 \mu\text{m}$, which could be produced by the unburnt helium (He I $\lambda 1.0830 \mu\text{m}$) in the outermost ejecta expanding at a high velocity ($\approx 26,000 \text{ km s}^{-1}$). At the same epoch, the Ca II IRT also exhibits similarly high velocities ($\approx 24,000 \text{ km s}^{-1}$). By now, we have a very small sample of four candidate He-shell DDet SNe which have NIR spectra observed. Interesting, all of them show deep absorption features near $1 \mu\text{m}$, which, if assumed to have a helium origin, would be expanding very a similar velocity as the high velocity component of Ca II IRT, despite the huge diversity in the Ca II IRT velocity (from $\approx 15,000 \text{ km s}^{-1}$ in SN 2016dsg to $\approx 24,000 \text{ km s}^{-1}$ in SN 2020jgb) in our tiny sample. Such a consistency in velocities of absorption lines would be naturally explained if it is the unburnt helium and the newly synthesized calcium from the He-shell that produce these line features. However, we could not find unambiguous evidence for other He I absorption lines, such as He I $\lambda 2.0581 \mu\text{m}$, so we are not drawing a strong conclusion of helium detection in SN 2020jgb. Nonetheless, we discuss other potential strong lines (Mg II, C I, Fe II) that may cause the $1 \mu\text{m}$ feature, but have found them also not that likely. Helium is still the most promising candidate.

This paper provides a framework of robust He I detection in He-shell DDet SNe. Ideally, one will need a NIR spectrum covering both the $1 \mu\text{m}$ and $2 \mu\text{m}$ regions in search of the He I $\lambda 1.0830 \mu\text{m}$ and $\lambda 2.0581 \mu\text{m}$ features. Since the He I $\lambda 2.0581 \mu\text{m}$ is weaker or even invisible when the He-shell is thin (Boyle et al. 2017), and could be blended with strong telluric lines, one should not always expect to see significant absorption features near $2 \mu\text{m}$. For those with a clear $1 \mu\text{m}$ feature, one can calculate the required velocity for an origin in He I $\lambda 1.0830 \mu\text{m}$, to see if it is comparable with the velocity with the HVFs in the Ca II IRT at a similar phase. While the detonation recipe in a DDet model and the viewing angles would all affect the observed He I velocity, we still expect the elements along the line-of-sight to expand at a similar pace, if they all have a He-shell origin. Excluding the possibility of other strong lines is also necessary, especially when the NIR spectrum is obtained before the peak of the SN, when there can be strong Mg II and C I absorption (Hsiao et al. 2019).

In the tiny sample of DDet candidates to date, we have seen diversity in observational properties, including the

Figure 7. *Left:* Comparison of the photometric evolution of SN 2020jgb with the He-shell DDet models from Polin et al. (2019). The model parameters are indicated in the legend as (C/O core mass + He shell mass). The upper (lower) panel shows the evolution in g -band (r -band) absolute magnitudes. *Right:* Comparison of the spectrum of SN 2020jgb with the $0.87 M_{\odot}$ C/O core + $0.08 M_{\odot}$ He-shell DDet model before peak luminosity. Each spectrum is normalized by the median flux between 6500 and 7500 Å, and binned with a size of 10 Å. The synthetic spectrum 4 days before the r -band peak best matches the NOT spectrum (Galactic extinction corrected), which was obtained ~ 4 days before the r_{ZTF} -band peak. All the phases have been rescaled to the host galaxy rest frame.

peak luminosity, color evolution, chemical abundances and line velocities, which could be explained by a large variety of He-shell masses, WD masses, viewing angles, and the initial chemical compositions in the shell. In addition, they are discovered in both old and young stellar populations, SN 2020jgb being the first unambiguous thick He-shell DDet candidate in a star-forming galaxy, suggesting their possible origins in a mixture of formation channels and progenitor systems.
